Physical activity, obesity and eating habits can influence assisted reproduction outcomes.

OBJECTIVE: To determine if eating habits, physical activity and BMI can influence assisted reproduction outcomes. MATERIAL AND METHODS: This study analyzed 436 patients undergoing intracytoplasmic sperm injection cycles. Patients answered a questionnaire and regression analysis examined the relationship between lifestyle and BMI with the intracytoplasmic sperm injection cycles outcomes. RESULTS: No influence of lifestyle and obesity was observed on the number of oocytes recovered. Obesity reduced the normal fertilization rate (coefficient [Coef.]: -16.0; $p = 0.01$) and increased the risk of miscarriage (OR: 14.3; $p = 0.03$). Physical activity positively affected implantation (Coef.: 9.4; $p = 0.009$), increased the chance of pregnancy (OR: 1.83; $p = 0.013$) and tended to decrease the risk of miscarriage (OR: 0.30; $p = 0.068$). In addition, an inverse correlation was found between physical activity and BMI, and a direct correlation was found between soft-drink consumption and BMI. CONCLUSIONS: Eating habits, physical activity and obesity could affect clinical outcomes of assisted reproduction.
